

Arrays of Josephson junctions between unconventional superconductors

D. V. Khveshchenko and R. Crooks

Department of Physics and Astronomy, University of North Carolina, Chapel Hill, NC 27599

We study large arrays of mesoscopic junctions between gapless superconductors where the tunneling processes of both, particle-hole and Cooper, pairs give rise to a strongly retarded effective action which, contrary to the standard case, can not be readily characterized in terms of a local Josephson energy. This complexity is expected to arise in, e.g., the grain boundary and *c*-axis junctions in layered high- T_c superconductors. A new representation for describing collective phenomena in this system is introduced, and its phase diagram is discussed, alongside the electrical conductivity.

Quantum dynamics of ultrasmall normal and superconducting (Josephson) junctions (JJ) has long been a field of active theoretical¹ and experimental² research. Recently, the interest in this topic has been rekindled by a number of new ideas, such as the proposal of a novel 'floating' phase, in which context the effects of (spatially) long-range correlations were investigated at a greater length³.

Notably, though, most of the previous theoretical studies were limited to the JJs between conventional, fully gapped, *s*-wave superconductors. Although the case of the *d*-wave superconducting cuprates, such as bi-epitaxial grain boundary (in-plane) JJs in *YBCO* or intrinsic *c*-axis (vertical) ones in *Bi2212*, have been rather extensively studied as well, their previous analyses would rou-

tinely resort to a phenomenological description similar to that of the gapped (*s*-wave) superconductors⁴. In contrast, the microscopic analysis of a single *d*-wave JJ carried out in Refs.^{5,6}, showed that the processes of both, particle-hole and Cooper, pair tunneling can give rise to the equally non-local (in the time domain) terms in the effective action, thereby invalidating the very notion of a local Josephson energy.

In the present work, we study a large array of such JJs and look into the effects of a strong time dependence of the effective action on this system's phase diagram and corresponding behaviors.

The partition function of a generic single JJ introduced in Ref.¹ can be generalized to the case of an array by including both, self- and mutual-, capacitances

$$S = \int_0^{1/T} d\tau \frac{1}{2} \left[\sum_i C_{ii} \left(\frac{\partial \phi_i(\tau)}{\partial \tau} \right)^2 + \sum_{\langle ij \rangle} C_{ij} \left(\frac{\partial \phi_{ij}(\tau)}{\partial \tau} \right)^2 \right] - \sum_{\langle ij \rangle} \int_0^{1/T} d\tau \int_0^{1/T} d\tau' [\alpha(\tau - \tau') \cos(\phi_{ij}(\tau) - \phi_{ij}(\tau')) + \beta(\tau - \tau') \cos(\phi_{ij}(\tau) + \phi_{ij}(\tau'))], \quad (1)$$

where $\phi_{ij}(\tau) = \phi_i(\tau) - \phi_j(\tau)$ is the phase difference across the link $\langle ij \rangle$.

The double time integrals in (1) are governed by the kernels $\alpha(\tau)$ and $\beta(\tau)$ representing particle-hole and Cooper pair tunneling processes, respectively. To the leading order in the tunneling matrix element $T(k, k')$, they are given by the expressions

$$\begin{pmatrix} \alpha(\tau) \\ \beta(\tau) \end{pmatrix} = -2 \int \frac{d^D k d^D k'}{(2\pi)^{2D}} |T(k, k')|^2 \begin{pmatrix} \mathcal{G}_k(\tau) \mathcal{G}_{k'}(-\tau) \\ \mathcal{F}_k(\tau) \mathcal{F}_{k'}(-\tau) \end{pmatrix} \quad (2)$$

where $\mathcal{G}$ and $\mathcal{F}$ are the normal and anomalous electron Green functions, respectively.

The α -term describes (non-Gaussian) dissipation due to the Andreev quasiparticle tunneling whose effects have been extensively discussed in the previous works¹, while the β -term represents the processes of (in general, non-synchronous) pair tunneling. In the conventional (*s*-wave) superconductors, it decays as $\beta(\tau) \propto e^{-\Lambda|\tau|}$, thereby effectively reducing the last term in (1) to a

single time integral $E_J \int_0^{1/T} d\tau \cos 2\phi_{ij}(\tau)$ of what can then be identified as the local Josephson energy $E_J = \int_0^{1/T} d\tau \beta(\tau)$.

By contrast, in the case of a gapless superconductor one obtains strongly retarded kernels^{5,6}

$$\alpha(\tau)/\alpha = \beta(\tau)/\beta = 1/\tau^{2D-\eta} \quad (3)$$

where the prefactor in the β -kernel vanishes for any factorizable matrix element, $T(k, k') = f(k)f(k')$, of a symmetry other than the *s*-wave and, therefore, it can only be due to a non-factorizable contribution $\propto f(\vec{k} - \vec{k}')$ into $T(k, k')$.

In the two-dimensional case and under the condition of momentum conservation, $2D - \eta = 2$ (see Refs.^{5,6}), hence both the tunneling terms appear to be marginal, the corresponding coupling constants α and β being dimensionless numbers of order unity. A short-time divergence of Eqs.(3) can be naturally regularized by substituting $\tau \rightarrow \sqrt{\tau^2 + \Lambda^{-2}}$ where the cutoff scale Λ is set by the maximal superconducting gap in the bulk.

Conceivably, one can encounter even longer-ranged correlations ($2D - \eta < 2$) in the presence of, e.g., resonant tunneling through zero energy states supported by certain tunneling configurations, such as that of the $d_0/d_{\pi/4}$ in-plane grain boundary⁷.

Turning now to the effective action (1), we find that a strongly retarded nature of the tunneling terms renders a customary dual representation based on the Villain transformation of the local Josephson term inapplicable, thereby making this model unsuitable for the standard mapping onto an effective vortex plasma¹. Therefore, a well-known description of the different phases in terms of bound vortex-antivortex complexes (dipoles, quadrupoles, etc.) can not be readily generalized to the

problem at hand, either, thus forcing one to take a different approach.

To that end, we introduce a new bosonic field $\psi_i(\tau)$, alongside an associated Lagrange multiplier field enforcing the local constraint $\psi_i(\tau) = e^{i\phi_i(\tau)}$. This approach should be contrasted with the previously developed treatments of the conventional (local) Josephson term (see, e.g., Ref.⁸) where a constrained bosonic variable would be used to represent the *pair* field $e^{2i\phi_i(\tau)}$. Indeed, an attempt to implement this technique in the present (non-local) case would require one to work with a technically intractable bi-local composite operator $\psi_i(\tau)\psi_i(\tau')$.

By integrating out the phase variable ϕ_i , keeping the leading terms of the corresponding cluster expansion (cf. with Ref.⁸), and then integrating out the Lagrange multiplier field, one arrives at the partition function

$$Z = \int D\psi_i^\dagger(\tau) D\psi_i(\tau) D\lambda_i(\tau) \exp\left(- \sum_{\langle ij \rangle} \int_0^{1/T} d\tau_1 \int_0^{1/T} d\tau_2 \psi_i^\dagger(\tau_1) [W_{ij}^{-1}(\tau_1 - \tau_2) + \delta_{ij} \lambda_i(\tau_1) \delta(\tau_1 - \tau_2)] \psi_j(\tau_2) \right. \\ \left. + \alpha(\tau_1 - \tau_2) \psi_i^\dagger(\tau_1) \psi_j^\dagger(\tau_2) \psi_i(\tau_2) \psi_j(\tau_1) + \beta(\tau_1 - \tau_2) \psi_i^\dagger(\tau_1) \psi_i^\dagger(\tau_2) \psi_j(\tau_2) \psi_j(\tau_1) + h.c.)\right) \quad (4)$$

where $\lambda_i(\tau)$ is an additional Lagrange multiplier enforcing the auxiliary constraint $\psi_i^\dagger(\tau)\psi_i(\tau) = 1$ (the latter is not automatically satisfied, unless the integration over $\phi_i(\tau)$ is performed exactly).

The correlation function appearing in Eq.(4)

$$W_{ij}(\tau) = \left\langle e^{i\phi_i(\tau)} e^{-i\phi_j(0)} \right\rangle = \exp\left[- \int \frac{d\omega d^D k}{(2\pi)^{D+1}} \frac{1 - \cos(\omega\tau - \vec{k}\vec{R}_{ij})}{\omega^2 C(k)}\right] = \delta_{ij} e^{-E_c|\tau|} \quad (5)$$

is governed by the effective Coulomb energy $E_c = \int \frac{d^D k}{2(2\pi)^{D+1} C_k}$ proportional to the integral of the inverse capacitance $C_k = \sum_{\langle ij \rangle} C_{ij} e^{i\vec{k}\vec{R}_{ij}}$ which converges, provided that the capacitance matrix progressively decreases with the separation between the sites.

The frequency integral in Eq.(5) diverges for any $\vec{R}_{ij} \neq 0$ which dictates that the correlation function $W_{ij}(\tau)$ remains strictly local in the real space. Also, Eq.(5) is written in the limit of vanishing temperature, while at finite T a proper account of large phase fluctuations with non-trivial winding numbers makes this (as well as any bosonic) function periodic with a period $1/T$ by virtue of the substitution $\tau \rightarrow \tau - T\tau^2$ (see Ref.¹).

At $\alpha = \beta = 0$ one then obtains a bare (normal) Green function

$$G_{ij}^{(0)}(\omega) = \frac{2\delta_{ij}}{\omega^2/E_c + E_c}, \quad (6)$$

while for finite α and β the quantum charge fluctuations give rise to the corrections which can be incor-

porated into the normal $G_{ij} = \langle \psi_i \psi_j^\dagger \rangle$ and anomalous $F_{ij} = \langle \psi_i \psi_j \rangle$ Green functions obeying the usual Dyson's equations

$$\begin{pmatrix} G_{ij} \\ F_{ij} \end{pmatrix} = \begin{pmatrix} G_{ij}^{(0)} \\ 0 \end{pmatrix} + G_{ik}^{(0)} \sum_{kl} \begin{pmatrix} \Sigma_{kl} & \Delta_{kl} \\ \Delta_{kl} & \Sigma_{kl} \end{pmatrix} \begin{pmatrix} G_{lj} \\ F_{lj} \end{pmatrix} \quad (7)$$

where both the normal Σ_{ij} and anomalous Δ_{ij} self-energies can be computed as series expansions in powers of α and β .

The analysis of these expansions shows that they can be organized according to the powers of the inverse coordination number z (e.g., $z = 2D$ for a simple cubic lattice). In the leading approximation for $z \gg 1$, the self-energies are given by the equations

$$\Sigma_{ij}(\omega) = \int \frac{d\omega'}{2\pi} [\delta_{ij} \sum_l \alpha(\omega - \omega') G_{ll}(\omega') + (\alpha(0) + \beta(0) + \beta(\omega - \omega')) G_{ij}(\omega')] \\ \Delta_{ij}(\omega) = \int \frac{d\omega'}{2\pi} [\alpha(\omega - \omega') F_{ij}(\omega') + \delta_{ij} \sum_l \beta(\omega - \omega') F_{ll}(\omega')] \quad (8)$$

When ascertaining a general layout of the phase diagram of the JJ array, different components of the self-energy can serve as emergent order parameters. As such, one can distinguish between the local, $\Sigma_0 = \Sigma_{ii}$, and non-local, $\Sigma_1 = \frac{1}{z} \sum_\mu \Sigma_{i,i+\mu}$ (here the sum is taken over the z nearest neighbors), normal, as well the corresponding anomalous, $\Delta_0 = \Delta_{ii}$ and $\Delta_1 = \frac{1}{z} \sum_\mu \Delta_{i,i+\mu}$, self-energies.

Specifically, Σ_1 signals the onset of a metallic behavior (hopping between neighboring sites), Δ_0 manifests an incipient local pairing, Δ_1 serves as the precursor of superconducting coherence setting in across the entire JJ network, while a frequency-dependent part of the Σ_0 indicates the development of local time correlations.

With the on-site and nearest-neighbor terms taken into account, the spatial Fourier harmonics read

$$\begin{pmatrix} \Sigma(\omega, k) \\ \Delta(\omega, k) \end{pmatrix} = \begin{pmatrix} \Sigma_0(\omega) \\ \Delta_0(\omega) \end{pmatrix} + \begin{pmatrix} \Sigma_1(\omega) \\ \Delta_1(\omega) \end{pmatrix} \gamma(k) + \dots \quad (9)$$

where $\gamma(k) = \sum_{\mu} e^{ik\mu}$.

Eqs.(8) can be further improved by adding polarization corrections to the effective coupling terms

$$\begin{pmatrix} \tilde{\alpha} \\ \tilde{\beta} \end{pmatrix} = \begin{pmatrix} \alpha \\ \beta \end{pmatrix} + \begin{pmatrix} \Pi_E & \Pi_O \\ \Pi_O & \Pi_E \end{pmatrix} \begin{pmatrix} \alpha & \beta \\ \beta & \alpha \end{pmatrix} \begin{pmatrix} \tilde{\alpha} \\ \tilde{\beta} \end{pmatrix} \quad (10)$$

where the polarization functions $\Pi_{E,O}(\omega) = \int \frac{d\omega'}{2\pi} \Gamma_{E,O} G(\omega') G(\omega - \omega')$ include the vertex corrections $\Gamma_{E,O}$ arising from the even and odd numbers of non-crossing β -couplings

$$\begin{pmatrix} \Gamma_E \\ \Gamma_O \end{pmatrix} = \begin{pmatrix} 1 \\ \beta \end{pmatrix} + \begin{pmatrix} \beta^2 & 0 \\ 0 & \beta^2 \end{pmatrix} \begin{pmatrix} \Gamma_E \\ \Gamma_O \end{pmatrix} \quad (11)$$

With the vertex and polarization corrections included and in the absence of any emergent order parameters, the self-consistent equation for $\Sigma_0(\omega)$ reads

$$\Sigma_0(\omega) = z \int \frac{d\omega'}{2\pi} \tilde{\Gamma}(\omega') \frac{\tilde{\alpha}(\omega - \omega')}{G_0^{-1}(\omega') - \Sigma_0(\omega')} \quad (12)$$

The (static and spatially uniform) expectation value of the Lagrange multiplier $\lambda = \langle \lambda_i(\tau) \rangle$ can then be determined from the normalization condition $\int \frac{d\omega d^D k}{(2\pi)^{D+1}} G(\omega, k) = 1$.

In order to ascertain the locations of the putative phase boundaries we include a constant term $\Sigma_0(0) + \lambda$ into the definition of the renormalized Coulomb energy $\tilde{E}_c$ and expand Eqs.(8) to the first order in the emergent self-energies Σ_1 , Δ_0 , Δ_1 , as well as the derivative of the (linear) frequency-dependent part of $\Sigma_0(\omega)$. Threshold values of the couplings, beyond which such self-energy components develop, are then given by the eigenvalue equations

$$\begin{aligned} \Sigma_1(\omega) &= \int \frac{d\omega'}{2\pi} \Gamma[\tilde{\alpha}(0) + \tilde{\beta}(0) + \tilde{\beta}(\omega - \omega')] G_0^2(\omega') \Sigma_1(\omega') \\ \Delta_0(\omega) &= z \int \frac{d\omega'}{2\pi} \Gamma \tilde{\beta}(\omega - \omega') G_0^2(\omega') \Delta_0(\omega') \\ \Delta_1(\omega) &= \int \frac{d\omega'}{2\pi} \Gamma \tilde{\alpha}(\omega - \omega') G_0^2(\omega') \Delta_1(\omega') \\ \frac{d\Sigma_0(\omega)}{d\omega} &= z \int \frac{d\omega'}{2\pi} \Gamma \tilde{\alpha}(\omega') G_0^2(\omega') \frac{d\Sigma_0(\omega')}{d\omega'} \end{aligned} \quad (13)$$

FIG. 1. Left panel: The onset of the inter-site self energy Σ_1 and both on-site and inter-site anomalous self energies Δ_0 and Δ_1 . Right panel: phase diagram (see text)

In the case of marginal ('Ohmic') dissipation corresponding to $2D - \eta = 2$ the Fourier transforms of the (regularized) coupling functions behave as $\alpha(\omega)/\alpha = \beta(\omega)/\beta = \pi\Lambda e^{-|\omega|/\Lambda}$, thus resulting in only a weak frequency dependence of the self-energy at $\omega \ll \Lambda$.

The first three of the eigenvalue equations (13) then reduce to the algebraic ones

$$\begin{aligned} 1 &= (\Gamma_E^2 + \Gamma_O^2)(2\tilde{\beta} + \tilde{\alpha}) + 2\Gamma_E\Gamma_O(2\tilde{\alpha} + \tilde{\beta}) \\ 1 &= z \left(\Gamma_E^2\tilde{\beta} + 2\Gamma_E\Gamma_O\tilde{\alpha} + \Gamma_O^2\tilde{\beta} \right) \\ 1 &= \Gamma_E^2\tilde{\alpha} + \Gamma_O^2\tilde{\alpha} + 2\Gamma_E\Gamma_O\tilde{\beta} \end{aligned} \quad (14)$$

from which one determines the locations of the putative critical lines in the $\alpha - \beta$ plane (see Fig1).

Interestingly enough, Eqs.(14) suggest that for small α and large z the onset of local ('on-site') pairing upon increasing β may precede that of the metallic behavior, while for small β the inter-site ('bond') pairing emerges only at sufficiently large α .

The above observations suggest a general layout of the phase diagram presented in Fig.1. The region of small α and β with $\Sigma_1 = \Delta_0 = \Delta_1 = 0$ is interpreted as uniformly insulating (I), while the emergent order parameter $\Delta_0 \neq 0$ signals the onset of local superconducting pairing (LP) at $\beta \sim 1/z$. At still higher values of $\beta \sim 1$ one expects to enter a Josephson-like phase (J) with $\Delta_0, \Sigma_1 \neq 0$ but without global coherence. On the other hand, at $\alpha \sim 1$ the insulator gives way to the resistive phase (R) with $\Sigma_1, \Delta_1 \neq 0$ which supports both, Cooper pair and single quasiparticle, transport. Lastly, the uniformly superconducting phase (SC) with $\Sigma_1, \Delta_{0,1} \neq 0$ would eventually be attained at $\alpha, \beta \gtrsim 1$. It should be noted, though, that our predictions are based on the approximate perturbative analysis and, therefore, not all the putative phase boundaries may actually be present in the real system. In particular, there may or may not be a physical distinction other than a crossover between the J and LP phases, or the latter regime might be absent altogether (as it is for $z = 2$).

Such caveats notwithstanding, the overall behavior appears to be somewhat reminiscent of that in the standard (*s*-wave) case: the system can be nudged closer to the superconducting state by increasing either, the Cooper pair or particle-hole tunneling, the latter providing a mechanism for intrinsic dissipation which quenches phase fluctuations and promotes the classical Josephson effect.

Should, however, the tunneling β -term happen to decay even more slowly ($2D - \eta < 1$), the analog of the

effective Josephson energy would then diverge at large τ , thus making the infrared behavior essentially singular and possibly allowing for some drastic changes in the phase structure.

Conducting properties of the JJ array allow one to discriminate between the different phases. In particular, electrical conductivity can be computed as $\sigma_{\mu\nu}(\omega) = \frac{1}{i\omega} \frac{\delta^2 S[A]}{\delta A_\mu \delta A_\nu}$ with the use of the action of Eq.(1) in the presence of an external vector potential A_μ , resulting in

$$\sigma_{\mu\nu}(\omega) = \int_0^{1/T} d\tau [\alpha(\tau) \frac{1 - e^{i\omega\tau}}{\omega} \langle \cos(\nabla_\mu \phi(\tau) - \nabla_\nu \phi(0)) \rangle + \beta(\tau) \frac{1 + e^{i\omega\tau}}{\omega} \langle \cos(\nabla_\mu \phi(\tau) + \nabla_\nu \phi(0)) \rangle] + \dots \quad (15)$$

where the dots stand for 'paramagnetic' terms containing higher powers of α and β which, therefore, are small compared to the above ('diamagnetic') contributions for $\alpha, \beta \lesssim 1$ (cf. with the discussion of a normal granular metal where $\beta = 0$ in Ref.⁹).

The thus-obtained longitudinal conductivity reads

$$\sigma_{\mu\mu}(\omega) \approx \int_0^{1/T} d\tau [\alpha(\omega) \frac{1 - e^{i\omega\tau}}{\omega} [G_1^2(0) + G_0^2(\tau) + F_1^2(\tau)] + \beta(\omega) \frac{1 + e^{i\omega\tau}}{\omega} [G_1^2(0) + G_1^2(\tau) + F_0^2(\tau)]] \quad (16)$$

and, upon performing the frequency integrations, one obtains

$$\sigma_{\mu\mu}(\omega) \approx \alpha \left[\frac{2E_c}{T} e^{-2E_c/T} \left(1 + \frac{\Delta_1^2}{E_c^2} \right) + \frac{\Sigma_1^2}{E_c^2} \right] + \beta \delta(\omega) \frac{\Sigma_1^2 + \Delta_0^2}{E_c} \quad (17)$$

where, for the sake of simplicity, we chose $T \ll E_c = \Lambda$.

The emergent metallicity order parameter Σ_1 promotes a metal-like (temperature-independent at $T \rightarrow 0$) conductivity, thereby distinguishing it from the activation-type behavior characteristic of the insulating regime. Interestingly enough, it also contributes to the superfluid density, alongside the local pairing Δ_0 , while the non-local one (Δ_1) does not (to the lowest order in β).

It is conceivable, though, that there might be a (partial) cancellation between the 'diamagnetic' and 'para-

magnetic' terms at $\alpha, \beta \sim 1$, as a result of which the conductivity could remain universal along the critical lines, akin to the situation in the conventional, *s*-wave, JJ networks¹⁰ (it is worth reiterating that in the present case one can not readily invoke the charge-vortex duality on which the universality argument is based¹ due to the inapplicability of the underlying Villain transformation).

To summarize, in the present work we studied arrays of unconventional JJs with long-range (in the time domain) interactions stemming from the presence of gapless quasiparticle excitations. On the technical side, the problem presents a new challenge by not being amenable to the customary approaches exploiting the intrinsic locality of the standard Josephson effective action.

By using an alternative representation, we find that the phase diagram of the system might feature the insulating, uniformly superconducting, Josephson (local pairing only), and metallic phases which can be identified by the corresponding emergent order parameters. We also predict that this picture might be further altered in the presence of resonant tunneling between zero energy states where the temporal decay of correlations can be even longer-ranged.

We conclude by expressing a hope that this analysis will prompt a further investigation into (and provide an alternative means for interpreting the experimental data on) the assemblies of high- T_c JJs beyond the scope of the customary phenomenological approach adapted from the earlier studies of the *s*-wave superconductors.
